- §1 Introduction to Deep Learning in Python
- §1.2 Optimizing a neural network with backward propagation
- §1.2.1 The need for optimization

1. How to measure the baseline for the neural network?

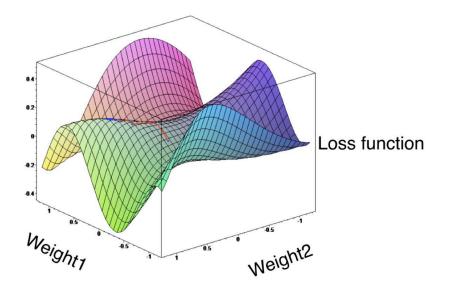

2. What are the challenges for the predictions with multiple points?

- Making accurate predictions gets more challenging with more points.
- At any set of weights, there are many values of the error corresponding to the many points for making predictions.

3. What is the importance of the loss function?

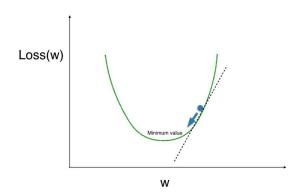

- Aggregates errors in predictions from many data points into a single number for measuring the model's predictive performance.
- A lower loss function value means a better model.
- The loss function's goal is to find the weights that give the lowest value for the loss function by gradient descent.

4. What are the steps of gradient descent?

Start at a random point until got somewhere flat, find the slope, take a step downhill.

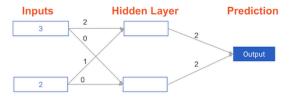

5. How to optimize a model with a single weight?

6. Practice question for calculating model errors:

• What is the error for the following network using the ReLU activation function when the input data is [3,2], and the actual value of the target is 5?

Error = Predicted - Actual

 \square 5.

 \Box 6.

□ 11.

 \square 16.

7. Practice question for understanding how weights change model accuracy:

• Imagine you have to make a prediction for a single data point. The actual value of the target is 7. The weight going from node_0 to the output is 2, as shown below. If you increased it slightly, changing it to 2.01, would the predictions become more accurate, less accurate, or stay the same?

- \square More accurate.
- \boxtimes Less accurate.
- \square Stay the same.
- 8. Practice exercises for the need for optimization:
- ▶ Diagram of the forward propagation:

► Code pre-loading:

```
def predict_with_network(input_data_point, weights):
    node_0_input = (input_data_point * weights['node_0']).sum()
    node_0_output = relu(node_0_input)

    node_1_input = (input_data_point * weights['node_1']).sum()
    node_1_output = relu(node_1_input)

    hidden_layer_values = np.array([node_0_output, node_1_output])
    input_to_final_layer = (hidden_layer_values * weights['output']).sum()
    model_output = relu(input_to_final_layer)
```

```
return (model_output)

def relu(my_input):
    return (max(0, my_input))
```

▶ Weight changes affect accuracy practice:

```
[2]: # The data point you will make a prediction for
     input_data = np.array([0, 3])
     # Sample weights
     weights_0 = {'node_0': [2, 1], 'node_1': [1, 2], 'output': [1, 1]}
     # The actual target value, used to calculate the error
     target_actual = 3
     # Make prediction using original weights
     model_output_0 = predict_with_network(input_data, weights_0)
     # Calculate error: error 0
     error_0 = model_output_0 - target_actual
     # Create weights that cause the network to make perfect prediction (3):
     \rightarrow weights 1
     weights_1 = {'node_0': [2, 1], 'node_1': [1, 0], 'output': [1, 1]}
     # Make prediction using new weights: model_output_1
     model_output_1 = predict_with_network(input_data, weights_1)
     # Calculate error: error_1
     error_1 = model_output_1 - target_actual
     # Print error 0 and error 1
     print(error_0)
     print(error_1)
```

6

▶ Data pre-loading:

```
weights_0 = {
    'node_0': np.array([2, 1]),
    'node_1': np.array([1, 2]),
    'output': np.array([1, 1])
}

weights_1 = {
    'node_0': np.array([2, 1]),
    'node_1': np.array([1., 1.5]),
    'output': np.array([1., 1.5])
}

target_actuals = [1, 3, 5, 7]
```

▶ Scaling up to multiple data points practice:

```
[4]: from sklearn.metrics import mean_squared_error
     # Create model_output_0
     model output 0 = []
     # Create model output 1
     model output 1 = []
     # Loop over input_data
     for row in input_data:
         # Append prediction to model_output_0
         model_output_0.append(predict_with_network(row, weights_0))
         # Append prediction to model_output_1
         model_output_1.append(predict_with_network(row, weights_1))
     # Calculate the mean squared error for model_output_0: mse_0
     mse_0 = mean_squared_error(target_actuals, model_output_0)
     # Calculate the mean squared error for model output 1: mse 1
     mse_1 = mean_squared_error(target_actuals, model_output_1)
     # Print mse_0 and mse_1
     print("Mean squared error with weights_0: %f" % mse_0)
     print("Mean squared error with weights_1: %f" % mse_1)
```

Mean squared error with weights_0: 37.500000 Mean squared error with weights_1: 49.890625
